Objectives: Most previous studies of the prevalence, incidence, and outcome of anorexia nervosa have been limited to cases detected through the health care system, which may bias our understanding of the disorder’s incidence and natural course. The authors sought to describe the onset and outcomes of anorexia nervosa in the general population.

Methods: Lifetime prevalences, incidence rates, and 5-year recovery rates of anorexia nervosa were calculated from the baseline data of 2,381 women from the 1975-1978 Finnish twin cohort study. Women who screened positive for eating disorder symptoms (N=282), their screen-negative female cotwins (N=1,194), and 219 randomly selected screen-negative women were assessed for lifetime eating disorder diagnoses by telephone by experienced clinicians. To assess outcomes after clinical recovery and to detect relapses of illness, women who had recovered were compared with their unaffected cotwins and healthy unrelated women on multiple outcome measures.

Results: The lifetime prevalence of DSM-IV anorexia nervosa was 2.3%, and half of the cases had not been detected in the health care system. The incidence of anorexia nervosa in women between 15 and 19 years of age was 2.4 per 100,000 person-years. The 5-year clinical recovery rate was 61.8%. Outcomes did not differ between detected and undetected cases. After clinical recovery, the remission of illness was steadily reduced. By 5 years after clinical recovery, most probands had reached complete or nearly complete psychological recovery and clinically resembled their unaffected co-twins and healthy women in weight and most psychological and social measures.

Conclusions: The authors found a substantially lower lifetime prevalence and incidence of anorexia nervosa than reported in previous studies, most of which were based on treated cases. Most women recovered clinically within 5 years, and thereafter usually progressed toward full recovery.

(Am J Psychiatry 2007; 164:1259-1269)

Anorexia nervosa is a severe psychiatric disorder that mainly affects adolescent girls and young women (1-5). Although the disorder was first described centuries ago, its etiology, genetics, and course remain poorly understood (1-5).

Numerous studies have assessed the prevalence of anorexia nervosa (4,5). Estimates of prevalence are influenced by the number of new-onset cases, but also by the diagnostic criteria, methods of case detection, and the age of study participants (6). Counting new-onset cases only, with liberal diagnostic criteria, is a more accurate approach to comparing rates of illness across communities and time periods and is essential for rigorous investigations of the etiology and course of illness (6). Despite this, few studies have examined the incidence of anorexia nervosa. Those that have been reported (7-10) reflect the difficulty of ascertaining relatively rare disorders: either they are limited to cases detected in health care settings or they lack statistical power because of small sample sizes. Nevertheless, they document a steady increase in the incidence of anorexia nervosa among 15- to 19-year-old women since the 1980s (8,11).

Long-term follow-up studies of anorexia nervosa are few and primarily reflect clinical case series or studies based on clinical catchment areas (12-14). They suggest that anorexia nervosa trials in a chronic course and carries high risk of mortality (about 5.8% per decade) (13,14). However, it has been estimated that only half of cases of anorexia nervosa are detected in primary care settings (15) and only one-third of the community cases are treated in mental health care settings (5), the natural course of the illness remains poorly understood.

Our aim was to describe the onset and outcomes of anorexia nervosa in the general population. Using the nationwide population-based 1975-1978 birth cohorts of Finland, we examined the incidence and lifetime prevalence of anorexia nervosa among twins. In order to understand the impact of anorexia on young women’s lives, we also compared the behavioral, psychological, and social outcomes of women with anorexia nervosa with those of their unaffected co-twins and unrelated healthy women.

Method

The "Finntwin 16" Birth Cohorts

Study subjects were Finnish twins participating in "Finntwins 16," a nationwide longitudinal cohort study of health behaviors in twins and their families (16) that identified virtually all live births.

Epidemiology and course of anorexia nervosa

FIGURE 1. Five-Year Clinical Recovery Rates From DSM-IV Anorexia Nervosa.

Results of Kaplan-Meier survival analysis. The 5-year clinical recovery rate was defined as the proportion who reached clinical recovery within 5 years after onset of illness. Clinical recovery was defined as remission of weight and menstruation and the absence of binging and purging for at least 1 year prior to assessment.

Participants: 200 women were interviewed at Wave 1 (mean age 17) and follow-up was conducted for up to 18 years. The waves were conducted at ages 17, 18, and between ages 22 and 28 (mean age 25.4, and 30.4, respectively). Data collection and analysis were approved by the ethics committee of the Department of Public Health of the University of Helsinki.

Questionnaire Screening for Eating Disorders

The wave 4 questionnaire included a self-report screen for eating disorder symptoms that assessed current height and weight, ideal weight, weight loss and gain, and weight loss behaviors. Body image was assessed by use of three subscales of the Eating Disorder Inventory (EDI)—body dissatisfaction, drive for thinness, and body dissatisfaction. All screen-positive answers to the wave 4 questionnaire (response rate 90.4%) and the response rate of respondents was 74.8% (95.4%). Details of the screening process are provided elsewhere (22).

Diagnostic Interviews

Five experienced clinicians (MDs and one R.N.) at the Eating Disorder Unit of Helsinki University Central Hospital received detailed training in administering the structured clinical interview for DSM-IV (SCID) (22). The interviews were conducted by telephone to obtain current and lifetime diagnoses of anorexia nervosa, bulimia nervosa, and binge eating disorder, to define the specific participants as the first and least common cases of illness, and to establish the temporal sequence of these diagnoses and their respective time course. The interviews were conducted by good consensus kappa-0.86 (range 0.6-1.0) (26). All inter-method and inter-rater performances were provided throughout the study and helped solve diagnostic problems, such as concerns about diagnostic threshold and differential diagnosis.

The interviews were conducted by 95.3% overall 90.3% for screen-positive women. All interviews were conducted by the same psychiatrists, and the screen-positive interviews were conducted by 72.8%. All interviews were conducted by the same psychiatrists, and the screen-positive interviews were conducted by 72.8%.

The wave 4 questionnaire included 5 screen-positive answers to the wave 4 questionnaire (response rate 90.4%) and the response rate of respondents was 74.8% (95.4%). Details of the screening process are provided elsewhere (22).

Outcomes After Clinical Recovery

The possible resolution of illness after clinical recovery was measured in five domains: physical, psychological, social, and cognitive. The physical characteristics were measured by self-report. Physical characteristics were measured by self-report. Physical characteristics were measured by self-report. Physical characteristics were measured by self-report. Physical characteristics were measured by self-report. Physical characteristics were measured by self-report.

In the evaluation of outcomes after clinical recovery, we compared probands with DSM-IV and broad anorexia nervosa with their unaffected female co-twins. "Unaffected" was defined as screening negative for eating disorder symptoms in the wave 4 questionnaire and not having a lifetime diagnosis of DSM-IV anorexia nervosa, bulimia nervosa, binge eating disorder, or eating disorder not otherwise specified in the SCID interview. Of the 98 co-twins in pairs discordant for broad anorexia nervosa, seven women had lifetime eating disorders. 12 were female co-twins who did not participate in the interview, and 28 were male co-twins from opposite-sex discordant twin pairs. After these individuals were excluded, 47 unaffected female co-twins remained.

Although unaffected co-twins are in many respects an ideal comparison group, they may differ from women in the general population. In order to detect any such differences that might be relevant to our conclusions, we drew a random sample of 105 female-female twin pairs (210 women) from the normative-referent women in these birth cohorts. Those who were also negative for all eating disorders in the SCID interview were deemed "healthy women" (N=90).

Statistical Analysis

Lifetime prevalences of DSM-IV and of broad anorexia nervosa were calculated by dividing the number of lifetime prevalent cases by the total number of women who responded to the eating disorder screen resident in the wave 4 questionnaire (N=2,463).

We compared the incidence rates of DSM-IV and of broad anorexia nervosa for the peak 5-year interval of risk (ages 15-19 years), as has been done in previous studies (3). For later age groups, the data were less reliable because of the small number of cases and varying ages at assessment. The numerator was the number of incident cases detected in the given age interval, and the denominator was the number of person-years at risk.

We used the Kaplan-Meier survival method to compute 5-year clinical recovery rates for DSM-IV and broad anorexia nervosa, and we used the log-rank test to compare survival rates across groups.

Psychological assessment after clinical recovery was analyzed in two ways. To examine trends toward full recovery, we calculated mean psychological outcome scales for women with DSM-IV anorexia nervosa who were clinically ill, those who had been in clinical recovery for 25 years, and the two comparison groups (unaffected co-twins and healthy women). These results were not adjusted for illness onset and illness duration. Next, we examine the trends toward full recovery after clinical recovery and to assess their statistical significance while also accounting for age at illness onset and illness duration, we designed a model that compared the probands and their unaffected co-twins as a function of time on the eight psychological outcome scales. To predict each outcome variable using a random intercept linear regression model and the following predictors: disorder status (we used only broad anorexia nervosa because of center constraints), age at illness onset, illness duration, time from recovery to interview for the proband (with linear and quadratic terms), and the same time variables for the co-twins. The random intercepts were included to account for dependence between twins. Age at onset, illness duration, and the time-dependent predictors for the unaffected co-twins were not found to be significant and were dropped from the final model.

For comparisons of physical and social characteristics between cases and comparison groups, we used analysis of variance for continuous outcome measures and logistic regression for categorical outcome measures. To account for clustered sampling within the twin pair, p values and confidence intervals in all analyses were adjusted using standard procedures for survey data (27). We used the statistical software Stata 9.2 (Stata Corp College Station, Tex.) for all analyses.

Results

Prevalence and Incidence

The lifetime prevalence was 2.2% (95% confidence interval [CI] 0.8-4.7) for DSM-IV anorexia nervosa (33 cases out of 1,525 women) and 4.2% (95% CI 3.4-5.0) for broad anorexia nervosa (107 cases out of 2,545 women). The incidence of DSM-IV anorexia nervosa for ages 15-19 years was 270 per 100,000 person-years (95% CI 180-360), and the incidence of broad anorexia nervosa was 486 per 100,000 person-years (95% CI 320-710).

Five-Year Clinical Recovery Rate

The 5-year clinical recovery rates were 60.8% and 66.1% for DSM-IV and broad anorexia nervosa, respectively (Figure 1). Overall, 79.3% women with DSM-IV anorexia nervosa and 76.6% with broad anorexia nervosa had reached clinical recovery by the time of the interview.

* Broad anorexia nervosa includes DSM-IV anorexia nervosa and ICD-10 atypical anorexia, here defined as anorexia nervosa without amenorrhea or weight loss of at least 15% that led to a BMI <18.5, coupled with other influences of body weight or self-evaluation in interior hair or weight gain. Detected cases are those in which the individual reported having received an eating disorder diagnosis from a qualified professional prior to lines having; undetected cases are those that did not receive such a diagnosis. Diagnostic status prior to this study was unknown for 14 women. The means were not adjusted for age of illness onset or illness duration.

FIGURE 2. Time-Dependent Psychological Outcomes of Broad Anorexia Nervosa Probands in Clinical Recovery Compared With Their Unaffected Co-Twins*  

Over time in clinical recovery, the mean psychological outcome scores of DSM-IV anorexia nervosa probands generally improved (Table 1). Using the broad definition of anorexia nervosa to maximize statistical power, we formally tested these observed trends. The null hypothesis was that outcomes of probands and co-twins do not converge, that is, that probands remain more symptomatic than their co-twins. We could reject the null hypothesis for s of six of the eight outcome measures: drive for thinness (z = -2.30, p = 0.021), bulimia (z = -2.23, p = 0.021), perfectionism (z = -2.30, p = 0.021), state anxiety (z = -2.23, p = 0.021), mood (z = -2.23, p = 0.021), and self-esteem (z = -2.23, p = 0.021). For the other two measures, there was no detectable convergence of proband and co-twin outcomes (mean dissatisfaction, z = -1.35, p = 0.18; psychosomatic symptoms, z = -1.32, p = 0.18). In other words, we found that the risk of illness seemed steady and statistically significantly over time for five of the eight psychological outcome measures, converging over time with their healthy co-twins’ outcomes' (Figure 2).

Neither the women who were currently ill with broad anorexia nervosa nor the probands who were in clinical recovery differed from their unaffected co-twins on education, occupation, or parity. The currently ill probands did differ from their unaffected co-twins in the proportion married or cohabiting with a partner (20.4% versus 55.1%, p = 0.011); the probands in clinical recovery showed a smaller and statistically nonsignificant difference from their unaffected co-twins on this measure (43.9% versus 52.1%)

**Detected Versus Undetected Cases**  
Approximately half of the cases ascertained in this study had been detected in the health care system. Detected cases constituted 53% (29 of 55) of all DSM-IV anorexia nervosa cases and 41% (44 of 107) of all broad anorexia nervosa cases.

Reproduced with permission of the copyright owner. Further reproduction prohibited without permission.
nervosa cases. The 5-year clinical recovery rates were similar for the detected and undetected cases; 61.8% versus 48.4%, respectively, for DSM-IV anorexia nervosa; and 60.1% versus 69.3%, for broad anorexia nervosa.

For broad anorexia nervosa, we had a sufficient number of cases in seven to compare the detected and undetected cases on numerous measures, including age at onset, minimum BMI, and psychological symptoms (Table 2). There were few differences between the detected and undetected cases, none statistically significant.

Unaffected Co-Twins Versus Healthy Women

The unaffected co-twins of broad anorexia nervosa probands were also compared with the healthy women from the same birth cohorts (Table 2), and the differences were not statistically significant. The frequency of bingeing or purging was similar in unaffected co-twins (32.1%) and healthy women (50.0%).

Discussion

In this population cohort of young women, there were three main findings. First, the incidence rate of anorexia nervosa was about twice as high as rates reported in prior studies. Second, the great majority of women who developed anorexia nervosa achieved clinical recovery within 5 years. Third, 5 years after clinical recovery, most women reached complete or nearly complete psychological recovery, closely resembling their unaffected co-twins and healthy women in weight and psychosocial measures.

Incidence Rates

The incidence rate of DSM-IV anorexia nervosa at ages 15–19 years was 2.7 per 100,000 person-years in the Netherlands (1). We propose five competing explanations for the high incidence rate: first, that anorexia nervosa was underestimated in prior studies, most of which were restricted to cases detected in the health care system; second, that anorexia nervosa was oversubscribed in this study; third, that anorexia nervosa is more common among twins than non-twin individuals because of unknown twin-specific exposures not shared by the general population; fourth, that the incidence rate of anorexia nervosa in Finland may be higher than in other countries; and fifth, that high incidence rates of anorexia nervosa were observed because of a cohort effect.

The first explanation predicts that our results should be similar to those of prior studies when we compute our incidence rates only on the basis of cases detected in the health care system. This prediction was borne out: the incidence of DSM-IV anorexia nervosa, based only on the detected cases, was 1.0 per 100,000 person-years at ages 15–19 years, which is similar to the figures cited above from the United States and the Netherlands. Also, our lifetime prevalences are well in line with earlier community-based observations from the United States (20) and Australia (20).

The second explanation predicts that no cases misclassified as cases of anorexia nervosa (undetected cases) should have a less severe and clear-cut illness than true (detected) cases. This prediction was not borne out: the undetected and the detected cases exhibited striking psychopathology and recovery rates.

The third explanation predicts that anorexia is more common among twins than non-twin individuals. However, previous research has found that rates of psychiatric disorders in twin and control populations are comparable (20). In this study, we found no differences in the diagnostic distribution and outcomes of broad anorexia nervosa by zygosity, and most cases were from discordant twin pairs. We also observed no appreciable differences in mortality and cohabitation frequency, body dissatisfaction, or psychosomatic symptoms between monozygotic and dizygotic healthy women (data available from first author).

Our data thus suggest that the incidence of anorexia nervosa has been substantially underestimated in previous studies, because a large proportion of true cases of anorexia nervosa remain undetected (3, 18), even in countries with highly developed and universal health care systems, such as Finland. More research on the patterns of help-seeking behavior in women with anorexia nervosa is warranted.

The other two possible explanations cannot be directly tested by our study. The first is that the incidence rate of anorexia nervosa in Finland may be higher than in other countries. However, recent research has found lifetime prevalences of anorexia nervosa comparable to ours, although they did not assess incidences of anorexia nervosa (4, 26, 29). The second is that the high incidences of anorexia nervosa we detected may in part reflect a secular

Epidemiology and Course of Anorexia Nervosa

A trend that is specific to recent birth cohorts, Bulik et al. (4) recently demonstrated that the prevalence of anorexia nervosa is greater among Swedes born after 1945 than it was among their mothers. The incidence of anorexia nervosa also has risen linearly in the United States and in the Netherlands in recent decades (9-11).

Clinical Recovery Rates.

The 5-year clinical recovery rate of anorexia nervosa in our study was higher than rates reported by most, though not all, previous studies. A recent review of 119 clinical outcome studies found that 41% of participants with anorexia nervosa achieved first-time recovery (14). Recovery rates increased significantly with follow-up time. In studies that recorded 5- to 6-year recovery rates from anorexia nervosa, the proportion achieving clinical recovery ranged from 35% in 80% of participants; the use of different definitions of clinical recovery probably contributed to the variability of the recovery rates (31-36). In this study, more than two-thirds of the women with DSM-IV anorexia nervosa achieved clinical recovery within 5 years. Despite this, the burden of illness was considerable: in almost two-thirds of the cases, the illness duration was 22 years, and in half, it was 23 years.

Outcomes After Recovery.

Rather than simply relying on our evaluation of clinical recovery, we were able to compare broad anorexia probands with their unaffected co-twins and healthy women on multiple measures. Probands with broad anorexia nervosa in clinical recovery could not be distinguished from their unaffected co-twins and healthy women in self-reported BMI, or on measures of social function. They still differed from their unaffected co-twins on eight measures designed to capture psychological characteristics. Over time, however, these residuals of illness remained. On six of the eight measures, the probands progressed to full recovery. The pattern was less clear for the other two measures of psychological characteristics: body dissatisfaction and psychosomatic symptoms appeared to be more persistent in the probands. Future follow-up waves will establish whether these differences diminish over time.

Limitations.

Selection bias due to differential participation of cases and noncases of anorexia nervosa in the telephone interviews is possible but likely minimal. Telephone numbers were obtained by letters sent to addresses updated from the Finnish population registry (response rate, 90.4%). The telephone interview participation rate of women with self-reported eating disorders was 89.1%, while that of healthy women was 89.8%.

The impact of selection bias on outcome could not be directly assessed in this study. We found that the detection of broad anorexia nervosa by the health care system had no association with prognosis in this study. This result does not, however, demonstrate that treatment had no effect, because case detection does not necessarily imply treatment or proper treatment.

We did not assess mortality, because the number of cases was small and the follow-up did not extend beyond ages 22-28 years. Previous studies have shown that the risk of mortality increases as a function of illness duration (16). Only a third of women with an atypical co-twin or no co-twin in our study had eating disorder symptoms for more than 5 years; and only 8.4% (N=19) had them for more than 10 years. Thus, estimates of anorexia nervosa-related mortality in this birth cohort will be more meaningful when linkage with mortality and cause-of-death registries is conducted. It is worth noting, nonetheless, that the overall mortality in this cohort was very low: only eight deaths occurred in the population registry between the first assessment wave at age 16 and the fourth wave at ages 22-28. In the worst case scenario, if all the deaths in the cohort were due to anorexia nervosa, the crude mortality rate of 0.2% per decade would be markedly lower than those recorded in follow-up studies of anorexia nervosa in clinical settings (37, 15-17), although they would be in line with community-based and national registry-based observations (38-40).

Conclusion.

In this population study, the incidences of DSM-IV and broad anorexia nervosa were much higher than rates reported previously. The 5-year clinical recovery rates were higher than those reported in most previous studies. Nonetheless, the burden of illness was remarkable. After clinical recovery, the residual of illness broadly classified: women closely resembled their unaffected co-twins on most measures after 5 years in clinical recovery, which demonstrates that full psychological recovery is both possible and likely.
